ABSTRACT

Derived radar reflectivities and fall speeds for four Weather Research and Forecasting (WRF) Model bulk microphysical parameterizations (BMPs) run at 1.33-km grid spacing are compared with ground-based, vertically pointing Ku-band radar, scanning S-band radar, and in situ measurements at Stony Brook, New York. Simulations were partitioned into periods of observed riming degree as determined manually using a stereo microscope and camera during nine winter storms. Simulations were examined to determine whether the selected BMPs captured the effects of varying riming intensities, provided a reasonable match to the vertical structure of radar reflectivity or fall speed, and whether they produced reasonable surface fall speed distributions. Schemes assuming nonspherical mass-diameter relationships yielded reflectivity distributions closer to observed values. All four schemes examined in this study provided a better match to the observed, vertical structure of reflectivity during moderate riming than light riming periods. The comparison of observed and simulated snowfall speeds had mixed results. One BMP produced episodes of excessive cloud water at times, resulting in fall speeds that were too large. However, most schemes had frequent periods of little or no cloud water during moderate riming periods and thus underpredicted the snowfall speeds at lower levels. Short, 1-4-h periods with relatively steady snow conditions were used to compare BMP and observed size and fall speed distributions. These limited data suggest the examined BMPs underpredict fall speeds of coldtype snow habits and underrepresent aggregates larger than 4-mm diameter.

1. Introduction

As operational numerical weather prediction continues a trend toward finer spatial resolution, bulk microphysical parameterizations (BMPs) are relied upon to capture numerous microphysical processes and characteristics of the resulting precipitation. Several

snow growth region (Garvert et al. 2005; Lin and Colle 2009). The snowfall speed was found to be too fast in the Purdue Lin (Lin and Colle 2009) and WRF singlemoment, 6-class scheme (WSM6; Hong et al. 2006) when compared to the Thompson et al. (2004) scheme. The revised Thompson et al. (2008) scheme (THOM2) incorporated a new mass-diameter relationship and particle size distribution for snow. Lin and Colle (2011) developed the single-moment Stony Brook scheme (SBU-YLIN), which combines the snow and graupel categories into a single precipitating ice class with corresponding riming factor. When compared against THOM2 and the Morrison et al. (2009) scheme (MORR), Lin and Colle (2011) found that the Stony Brook scheme reduced snow amounts aloft, which compared more favorably with in situ observations acquired over the Oregon Cascades.

Other examinations of simulated and observed snowfall were performed using observations from the Canadian CloudSat/Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) Validation Project (C3VP) in Ontario (Skofronick-Jackson et al. 2015; Petersen et al. 2007). Snowfall observed during the 22 January 2007 event comprised primarily lightly rimed dendrites and their aggregates and was sampled by ground-based and aircraft observations. Molthan et al. (2010) used C3VP in situ observations and radar observations from 22 January 2007 to evaluate the Goddard 6-class scheme with graupel (Tao et al. 2003; Lang et al. 2007) and Molthan and Colle (2012) extended the evaluation to include the WSM6, THOM2, MORR, and SBU-YLIN schemes. Their studies generally concluded that schemes providing greater flexibility in size distribution parameters, density, or additional moments improved performance over the use of constant, assumed parameters. Surface measurements of particle fall speeds during the C3VP event suggested that diameter-velocity parameterizations of the THOM2, MORR, and WSM6 schemes overestimated fall speeds for sizes larger than 1 mm, while the SBU-YLIN scheme produced fall speeds closest to the observations (Molthan and Colle 2012). Meanwhile, the Goddard scheme tended to underestimate fall speeds for all sizes (Molthan et al. 2010). Whereas the Goddard scheme tended to underestimate fall speeds in Molthan et al. (2010), Han et al. (2013) found it provided the best agreement with observations acquired in snowfall located above the melting layer of a broader region of stratiform rainfall, which preceded a cold front affecting western California. Shi et al. (2010) evaluated the performance of the Goddard scheme for lake-effect snow observed during C3VP through comparisons of observed and simulated C- and W-band radar reflectivities and AMSU-B brightness temperatures. Comparisons of simulated and

observed radar reflectivities demonstrated that for lakeeffect bands, the WRF simulation underestimated the echo-top height of the observed band and failed to identify numerous, smaller cores of reflectivity. For broader regions of synoptic-scale precipitation, there was a tendency to overestimate the coverage of the reflectivity above 20 dBZ. Additional analysis of reflectivity contoured frequency by altitude diagrams (CFADs) revealed an overall ability for their simulation to capture the overall large-scale cloud structures but additional refinements to microphysics and smaller-scale features were needed.

Regional differences in scheme performance highlighted in the aforementioned studies warrant additional evaluations for other phenomena. Studies have evaluated snow and graupel characteristics within BMPs for events in California, the Pacific Northwest, the Appalachians, and southern Ontario, but no known studies to date have examined BMP assumptions in simulations of winter storms in the northeastern United States. Recent studies have documented the evolution of snowfall microphysics in such storms as a precursor to model comparisons. Stark et al. (2013) observed the evolution of ice crystal habits through stereo microscope observations of snow obtained at the surface, corroborated by WSR-88D cross sections and a vertically pointing Doppler radar. The degree of riming for ice crystals was assessed from stereo microscope particle images (Mosimann et al. 1994). The degree of riming and the prevalence of dendrites increased with snowband maturity and intensity, corresponding to an increase in the snow-toliquid ratio, precipitation, and fall speed. As snowbands passed, weaker ascent and lower relative humidity values corresponded to platelike crystals, an overall decrease in dendrites, and less riming. Colle et al. (2014) surveyed a dozen winter cyclones across three seasons that impacted the northeastern United States and related snow-to-liquid ratios to predominant crystal habits and the degree of riming. Dominant crystal habits and variability in riming were noted in relation to frontal zones and the distance from the cyclone center; thus, a single event is likely to comprise periods of varying habit, degree of riming, and snow-to-liquid ratio.

In this study, model simulations of events documented by Stark et al. (2013) and Colle et al. (2014) are categorized by the degree of riming present in surface observations of snowfall. For each 15-min period, an average degree and range of riming was determined by visual inspection of stereo microscope images. This time series is then used to partition radar observations and model output to represent times when light and moderate riming occurred over the observation site. Model performance is then assessed with respect to the TABLE 1. Snow particle fall speed variables. Vertical air motion is *w* and turbulence is *E*. In the third and fourth equations below, *w* is assumed to be constant within a radar resolution volume and a WRF Model grid box.

observed degree of riming from multiple storms and multiple seasons. Four BMPs are selected based upon their diverse means of characterizing snow size distributions, fall speed relationships, means for graupel production, and simulation of riming characteristics (Molthan and Colle 2012, Tables 1 and 2). Schemes were selected based upon their frequent use in operational numerical weather prediction and for continuity with the previous study to suggest continued improvements in the simulation of winter weather. Since detailed in situ aircraft observations are not available for this multiseason sampling of storms, evaluations are performed against available ground observations and radar remote sensing of the reflectivity and particle fall speed. Model simulations of these quantities and comparison to observations will clarify whether these schemes capture variability in the size distribution and fall speed during periods of varying riming degree, which is necessary to improve simulations of winter precipitation. Comparisons will also identify future opportunities for improvement in the simulation of riming processes.

This study is motivated by two key research questions:

- How realistic are selected single- and double-moment WRF BMPs for simulating snow size distributions, fall speeds, and radar reflectivity for observed periods of light and moderate riming during winter storms over Long Island, New York?
- How does the WRF BMP performance change for these categories of observed riming, and when large aggregates are present?

This paper is organized as follows. Section 2 will discuss the data and methods used in this study. Section 3 will discuss the model verification results, and the conclusions are presented in section 4.

2. Data and methods

This study uses several computed and observed variables related to snow particle fall speed, which we define in Table 1 for clarity. Differences in these variables need to be taken into account when comparing among them. Since the instruments available did not directly observe small-scale turbulence E and vertical air motion w, we can only directly compare among the measured and computed values when we can assume E and/or w are zero. In low horizontal wind conditions, it is often assumed that w = 0 for surface-based in situ instruments such as disdrometers. Surface observations for events described herein were limited to periods of horizontal wind speeds of $5 \,\mathrm{m \, s^{-1}}$ or less. In these environments, small-scale turbulence E will be smaller than typical snowfall events, following Schreur and Geertsema (2008), who estimated E as related to half the squared difference of wind gust and average wind speeds.

a. Observations

Microphysical and radar observations for this study were taken during the 2009–12 winter seasons at Stony Brook, New York (SBNY; see Colle et al. 2014, their Fig. 1), which is on the north shore of Long Island (LI), approximately 93 km east of New York City, New York (NYC). Stark et al. (2013) and Colle et al. (2014) provide details on the experimental setup and location. A vertically pointing METEK Ku-band Micro Rain Radar (MRR; Peters et al. 2002) was used at SBNY to observe the profile of reflectivity and Doppler velocities to 7750 m above sea level every minute. The MRR has been used to study winter snowstorms in several locations (Cha et al. 2009; Keighton et al. 2009; Prat and Barros 2010; Kneifel et al. 2011a,b; Xie et al. 2012; Maahn and Kollias 2012, Stark et al. 2013; Colle et al. 2014; Maahn et al. 2014; Pokharel et al. 2014a,b; Garrett et al. 2015). The radar reflectivities from the short wavelength of the radar (1.25 cm) are subject to attenuation in heavier precipitation (Löffler-Mang et al. 1999) and in conditions when wet snow builds up on the antenna (Stark et al. 2013). The latter is the more relevant for conditions during snowstorms. The MRR data were postprocessed to improve sensitivity and data quality using the method of Maahn and Kollias (2012).

Observations from the MRR were supplemented by the WSR-88D at Upton, New York (KOKX). Vertical profiles of interpolated WSR-88D reflectivity were computed from level II KOKX data for the vertical column nearest the verification point of each model simulation. The WSR-88D data have a coarser native sensor spatial resolution, about 500 m in the vertical and horizontal at the 30-km range over the SBU site as compared to the MRR resolution volume size of 250 m in the vertical and ~100 m in the horizontal. For convenience in generating comparisons, the WSR-88D data were interpolated onto a Cartesian grid with vertical and horizontal spacings of 250 m and 100 m, respectively.

A Particle Size Velocity (PARSIVEL; Löffler-Mang and Joss 2000; Löffler-Mang and Blahak 2001; Yuter et al. 2006) disdrometer was placed about 1 m above the onestory roof surface to collect hydrometeor size and fall speed distributions. Battaglia et al. (2010) note that the PARSIVEL measures a "PARSIVEL diameter" based on the maximum shadowed area of the particle as it passes through the disdrometer laser beam. In a limited set of conditions where the snowflake is horizontally aligned, this measurement is equivalent to the widest horizontal dimension of the snow particle; otherwise, the PARSIVEL diameter represents an estimate of the widest horizontal diameter with an error less than or equal to 20%. In calm conditions, the PARSIVEL measurement of particle fall speed is equivalent to the settling speed (Table 1). Battaglia et al. (2010) determined that the PARSIVELmeasured fall speed has a variance of less than 20% for individual particles and tends to underestimate the mean fall speeds of smaller particles. The larger errors in their reported fall speeds are less relevant here as their

FIG. 1. WRF Model domains used in this study.

instruments were typically operated in windy conditions. Analysis herein was restricted to winter storms with winds less than $5 \,\mathrm{m \, s^{-1}}$ to avoid the potential for blowing snow from the surface impacting the results (D. Kingsmill 2011, personal communication) and to emphasize periods of reduced small-scale turbulence.

To further characterize precipitation during these events, a stereo microscope and camera were used to observe the snow habits and riming intensities at the SBU site as described in Colle et al. (2014) and Stark et al. (2013). The ice habits were categorized into several main types (needles and columns, dendrites, plates, side planes, and bullets), and riming was categorized as light, moderate, or heavy. Heavy riming did occur during short intervals within three sampled storms, but the sample size of heavy riming was insufficient for a comprehensive analysis.

b. WRF simulations

WRF (Skamarock et al. 2008) version 3.3 was utilized for simulations of several of the observed winter storms. The North American Mesoscale Forecast System (NAM) analysis dataset at 12-km grid spacing (NAM 218 hereafter) and 6-hourly time increments were used as initial and boundary conditions in the majority of the simulations; though in a limited number of events, the Global Forecast System (GFS) analysis data at 0.5° grid spacing were used because simulations with the NAM 218 data were too dry, or precipitation placement was not in agreement with the observations. Sea surface temperature and snow cover data were included in these initial and boundary condition datasets at model initialization. The WRF was run using an outermost 36-km-resolution domain with one-way nesting for three inner domains at 12-, 4-, and 1.33-km grid spacing as illustrated in Fig. 1. The 1.33-km domain was used in the

TABLE 2. Initialization time, total run time, and initial and boundary conditions used in the cases simulated with the WRF v3.3 model.

analysis for this paper. Thirty-nine vertical levels were used, and the top of the model was 100 hPa. Model physics included the Betts-Miller-Janjić cumulus scheme (Betts and Miller 1993; Janjić 1994) on the 36- and 12-km domains, the Yonsei University (YSU; Hong et al. 2006) planetary boundary layer scheme, and the Unified Noah land surface physics package (Ek et al. 2003). Within the 4- and 1.33-km resolution domains, a convective parameterization was not used, and all cloud or precipitation processes were simulated with the WSM6 (Hong et al. 2006), THOM2 (Thompson et al. 2008), SBU-YLIN (Lin and Colle 2011), or MORR (Morrison et al. 2009) bulk microphysics schemes. Molthan and Colle (2012, their Table 1) provide a detailed overview of the characteristics of snowfall within the WRF v3.3 schemes used in this study. The WRF model and BMPs were specially configured to output the particle size distribution intercept $N_{\rm os}$ and slope parameter λ_s of the snowfall size distributions, along with parameters necessary to obtain the radar reflectivity and radar-reflectivity-weighted fall speeds of precipitating species in each scheme. Molthan and Colle (2012) provide details on the derivation of the model reflectivity, size distribution parameters, and fall speeds.

A list of cases simulated, their respective initialization times, and their initial conditions are given in Table 2, which represents a subset of a larger number of storms evaluated by Colle et al. (2014). The verification point in the WRF Model was obtained through a bilinear interpolation of 1.33-km resolution grid boxes nearest to SBNY in each simulation. For the simulations of 19-20 December 2009, the simulated heavy snowband was approximately 58 km southwest of the actual location. In this case, a representative point for SBNY was selected relative to the simulated snowband. The verification points for each simulated case and BMP are shown in Table 3. With the exception of the 7 January 2011 event $(\sim 4 h)$, each simulation included at least 6 h of spinup time to generate precipitation prior to verification. Other simulations of the 7 January 2011 event with a longer startup time did not capture the precipitation that occurred over SBNY.

c. Comparisons of volumetric characteristics

Derivations of the model-derived reflectivities and fall velocities are straightforward and computed using assumptions consistent with each of the BMPs (Molthan and Colle 2012). Model-simulated properties were calculated for WRF grid boxes with at least $0.001 \,\mathrm{g \, kg^{-1}}$ of hydrometeor mixing ratio, thus, reflectivity and fall speed distributions correspond to model volumes with at least a trace of snow, graupel, or rain. Comparison of model output to observations is more complex as there are several limitations of the observations that preclude direct comparison. As noted previously, MRR observed reflectivity is subject to attenuation when snow accumulates on the MRR antenna. The differences in sensor spatial resolution between the MRR and WSR-88D will manifest most strongly when the storm structure is more spatially heterogeneous and nonuniform beam filling is present (Rinehart 1991). Though many schemes represent subgrid variability in clouds through a cloud fraction defined in both the microphysics and radiation schemes, their representation is not sufficient to account for the same effects of a nonuniformly filled or partially filled radar resolution volume. In addition, the modelderived reflectivities are not subject to instrument sensitivity constraints and can be computed for lower precipitation ice concentrations than can be detected by either of the two radars. The cm-wavelength MRR and

FIG. 2. Observed light or moderate riming periods and corresponding simulation times when model profiles were extracted for performing comparisons.

WSR-88D radars do not have sufficient sensitivity to observe the nonprecipitating portions of cloud.

We compare the radar reflectivity in the vertical column from the WRF Model directly over the SBU measurement site to the radar reflectivity observed by the MRR and to the vertical column of WSR-88D data from KOKX taken over the site. Simulations from the innermost, 1.33-km domain are separated into whether there was light, moderate, or heavy riming observed at SBNY (Colle et al. 2014). The set of these profiles is accumulated into an asynchronous volume of data from which joint frequency distributions of reflectivity and height using contoured frequency by altitude diagrams (CFADs; Yuter and Houze 1995). We truncate the observed CFADs for the MRR and WSR-88D at the altitude where the number of samples is less than 20% of the maximum number of samples at one level in the volume (Yuter and Houze 1995). Some differences existed in the specific timing between the simulated and observed precipitation, as shown in Fig. 2.

Similarly, we compare joint frequency distributions of measures of snowfall speed with height between the model column over the measurement site and the MRR. The MRR Doppler velocity is not directly equivalent to the model's computed mean fall speed. Errors in any combination of the model vertical air motion, size distribution, size–fall speed relation, and/or particle density would yield errors in the model-computed mean reflectivity-weighted fall speed ($V_{\rm ef}$; Table 1).

As a net result of these differences, we do not expect close quantitative matches between the model and observed Z or fall speed variables. Rather, we focus on the degree of agreement in the trends of the modes of the distributions with height and changes in the width of the distribution with height. We also note large differences in the trends in maximum Z values with height. The interplay among the model kinematics, microphysics, and latent heat release is such that it is not possible to attribute differences solely to individual components within the microphysics parameterizations such as size distributions and particle densities.

3. Model microphysical evaluation

a. Evaluation of simulations during observed light riming events

We first examine combined statistics from 21 occurrences of light riming within nine events (Fig. 2). For these time periods with the light riming designation, surface stereo microscope observations indicate that less than 1% of particles were graupel (Colle et al. 2014, their Fig. 6). Colle et al. (2014) showed that cold-type crystals (side planes and bullets, plates, and needles) were dominant (\sim 80%) during observed, light riming periods (\sim 80%), whereas the schemes examined assume slower-falling dendritic habits. Mean profiles and CFADs of simulated hydrometeor categories are shown in Figs. 3 and 4, respectively, for simulations sampled during observed periods of light riming. Mean profiles of cloud ice for the SBU-YLIN and MORR schemes are similar (Figs. 3a,d) and, frequently, less than $0.05 \,\mathrm{g \, kg^{-1}}$ within an altitude range of 4–9km (Figs. 4b,n). The WSM6 produces cloud ice throughout the column (Fig. 3b), in sharp contrast to the THOM2 scheme, which produces the smallest amount of cloud ice, confined to 6-10 km (Fig. 3c). In the THOM2 simulations, cloud ice mixing ratios were smaller than $0.05 \,\mathrm{g \, kg^{-1}}$, or a single CFAD joint histogram cell size (Fig. 4j). Though the four schemes differ in their partitioning of ice mass into cloud ice, snow, or precipitating ice, they produce a similar vertical distribution of total snow and ice mixing ratios. Partitioning of mixing ratios among these categories exaggerates some of their differences. Rather than simulating small crystals through the production of the cloud ice mixing ratio, the THOM2 applies a bimodal size distribution within the simulated snow category.

The MORR, WSM6, and THOM2 schemes produce mean cloud water profiles of 0.02 g kg^{-1} or less within the lowest 4 km (Figs. 3a–c), where mean temperatures range from -15° to 0° C (Fig. 5a). The SBU-YLIN scheme increases the mean cloud water throughout the column, to 0.06 g kg^{-1} at 4 km. The increased cloud water mixing ratio continues through 8 km, which is inconsistent with surface observations of lightly rimed particles (Fig. 3d). Cloud water CFADs capture infrequent amounts of cloud water content greater than

FIG. 3. Mean profiles of hydrometeor content for selected microphysics schemes and simulations sampled during observed periods of light riming shown in Fig. 2. Combined mixing ratios of cloud ice and snow are shown as a black dashed line.

the mean values for each scheme, predominately in the lowest 4 km (Fig. 4). Each scheme shows the greatest increases in mean snow (or precipitating ice) mixing ratios between echo top and 4 km, where the rate of increase slows and then decreases toward the surface. The MORR and WSM6 schemes produce graupel with mean profile amounts greater than $0.01 \,\mathrm{g \, kg^{-1}}$ confined to the lowest 4 km (Figs. 3a,b), with infrequent occurrences of amounts exceeding 0.25 g kg^{-1} (Figs. 4d,h). The THOM2 simulations produced very small amounts of graupel with mean values less than $0.001 \,\mathrm{g \, kg^{-1}}$. Graupel is produced by several and different processes within the MORR, WSM6, and THOM2 schemes; however, detailed microphysical process budgets for each simulation are beyond the scope of this study. The SBU-YLIN scheme represents snow and graupel through a rimed precipitating ice category but produces excessively high riming intensities as a result of excessive cloud water (Fig. 6a). The THOM2 scheme produces a larger mean profile of snow and occasional, larger amounts of snow mixing ratio than the MORR and WSM6 schemes that produce graupel. Median, liquid-equivalent precipitation from these schemes ranges from 0.1 to $0.2 \,\mathrm{mm}\,\mathrm{h}^{-1}$, with the highest amounts resulting from the WSM6 scheme (Fig. 7).

Figure 8 shows the frequency distributions of observed MRR and WSR-88D reflectivity (Z) along with values derived from WRF simulations during light riming periods. In the lowest 2 km, the most frequently occurring (modal) values of MRR reflectivity are around 16–20 dBZ (Fig. 8a), comparable to the WSR-88D reflectivity within the same altitude range (Fig. 8b). As compared to the MRR, the WSR-88D has a broader range of Z values at each height, with small occurrences of values that exceeded those observed by the MRR. The cause for the lack of Z values greater than 24–28 dBZ in the MRR dataset is not clear.

Simulated reflectivity is highly variable and lacks the distinct modes observed by the MRR and WSR-88D, suggesting that observed precipitation structures are more uniform at various altitudes than the corresponding model simulations during light riming events (Figs. 8c–f). Both the modal and maximum Z values observed by the WSR-88D increased between 6- and 1-km altitude, consistent with an increase in particle sizes via depositional growth and aggregation. The increase was from 8 to $18 \, \text{dBZ}$ for the modal values and 18 to $34 \, \text{dBZ}$ for the maximum values. The THOM2 scheme has a similar trend of maximum values with height, while the other three schemes have maximum reflectivities that are too high from 4 to 6km. The THOM2 and SBU-YLIN schemes produce reflectivity distributions comparable to observations in the lowest 4 km while the WSM6 and MORR schemes exceed the observed reflectivity distribution from the WSR-88D. The higher reflectivity values in the WSM6 and MORR simulations than observed likely result from the prediction of graupel, representing moderate to heavily rimed particles in contrast to the observed, light riming.

Figure 9 shows the distributions of observed Doppler velocity and simulated fall speed variables. Throughout the vertical column, there is a fairly consistent range in Doppler velocities observed by the MRR, from 0.3 to 2.0 m s^{-1} , and above 4-km altitude, the mode in MRR Doppler velocity is less distinct than lower levels (Fig. 9a). The most frequently observed Doppler velocities of around 1.0 m s^{-1} are consistent through an altitude of 4 km. There is broadening of the observed fall speed distribution to nearly 1.75 m s^{-1} below 2 km associated with the increased particle growth and reflectivity increase in this layer. The MORR and THOM2 fall speed distributions are narrower than observed below 2-km altitude (Figs. 9b,d), while the SBU-YLIN

FIG. 4. CFADs for hydrometeor species obtained from surveyed microphysics schemes during the light riming periods shown in Fig. 2. Mean profiles of each hydrometeor type are provided as a solid black line. Trace amounts of cloud ice and graupel in the THOM2 scheme are shown as mean profiles in Fig. 3. Note that the *x*-axis scale for the snow or precipitating ice column differs from the remaining panels.

(Fig. 9e) has a second mode below 5-km altitude at high fall speed values, which is inconsistent with the observations. Schemes incorporating a temperaturedependent size distribution, such as WSM6, THOM2, and SBU-YLIN, show trends of increasing fall speed with decreasing height between 3 and 7 km. The MORR scheme undergoes less of a change in fall speed with height and is more consistent with the observations. Unfortunately, lack of data from the MRR in the lowest 1 km precludes validation of the ~0.2 m s⁻¹ increase in fall speed peak frequency for the MORR. At 1–2 km, where the MRR provides observations, the MORR and WSM6 simulations provide the best match to MRR fall speeds ($\sim 1.0 \text{ m s}^{-1}$), while the THOM2 and SBU-YLIN slightly underestimated fall speeds by around 0.25 m s⁻¹.

b. Evaluation of simulations during observed moderate riming events

During moderate riming periods (21 occurrences within seven events; Fig. 2) the observed snow contained about 50% dendrites and plates, 20%–25% needles, less than 10% cold-type crystals, and small amounts (<4%)

FIG. 5. (left) Mean temperature profiles and standard deviations of temperature during periods of light and moderate riming shown in Fig. 2, and (right) difference of the mean temperature profile between moderate and light riming periods.

of graupel (Colle et al. 2014). All schemes increase their predicted mean snow and combined cloud ice and snow mass projections (Fig. 10), shown as a higher frequency of larger mixing ratios, particularly in the lowest 3–4 km (Fig. 11). Cloud water also increases in all schemes, particularly in the lowest 2 km, along with increases in the mean profile through 6 km. Increases occur across a range of temperatures from -15° to 0°C (Fig. 5a), where the simulations for these moderate riming events average as much as 1.5° C warmer than light riming cases (Fig. 5b). The MORR scheme exhibits an increase in mean cloud water and frequency from 1 to 4 km, where the mean temperatures range from -15° to -5° C, up to 1.5° C warmer than light riming cases. Overall, the most frequent mixing ratio of cloud water remains less than 0.1 g kg^{-1} , and the mean value is 0.05 g kg^{-1} or less for all schemes except the SBU-YLIN. The simulated cloud water amount is less than expected for periods of moderate riming. For example, Lin and Colle (2009) and Lin and Colle (2011) showed for two cases over the Washington Cascades that the observed and simulated cloud water was $0.1-0.3 \text{ g kg}^{-1}$ for moderate riming periods. Some of the cloud water in the SBU-YLIN scheme appears to be erroneously high (> 0.3 g kg^{-1}), resulting in heavily rimed precipitating ice, increased precipitation, and a decrease in snow mass by fallout in the lowest 3 km. Excess production of cloud water may be related to issues with the saturation adjustment process in the SBU-YLIN scheme (Molthan and Colle 2012). Although the aforementioned schemes produce some additional snow and cloud water, the MORR

and WSM6 simulations produce amounts and frequencies of graupel comparable to light riming simulations with similar maximum values and frequencies (Figs. 11d,h). Mean profiles of graupel in moderate riming events are similar to light riming events for the MORR, WSM6, and THOM2 profiles (Figs. 10a–c).

The CFAD of MRR reflectivity has a distribution mode below 2-km altitude that is sharper and greater than during light riming periods (20 dBZ; Fig. 12a). The modal value of the WSR-88D reflectivity in the lowest 2 km is similar at 20-24 dBZ (Fig. 12b). Both MRR and WSR-88D distributions of Z indicate a steady increase in the modal value of reflectivity with decreasing altitude from 6 to 2 km. Such "diagonalization" of the reflectivity CFAD indicates growth of particles as they descend (Yuter and Houze 1995). As with light riming cases, the CFAD of WSR-88D reflectivity included small frequencies of higher reflectivity near the surface, as high as 32-34 dBZ. Similarly, the MRR data included small frequencies of reflectivity from 24 to 28 dBZ. All four models exhibit clear modes in the reflectivity distribution that increased with decreasing height, similar to the diagonalization seen in the observations; though their modal values and ranges differ from the MRR and WSR-88D data. The MORR and WSM6 schemes (Figs. 12c,d) produce modal and maximum reflectivity exceeding WSR-88D and MRR observations near the surface (Figs. 12c,d). The THOM2 and YLIN schemes are a better match to the observed reflectivity values and trends with altitude in terms of modal and maximum values (Figs. 12e,f).

The MRR Doppler velocity distribution produces a mode that increases with decreasing altitude from to

 1.0 m s^{-1} at 4-km altitude to 1.25 m s^{-1} at the surface (Fig. 13a). The mode in the MRR near-surface Doppler velocity increases by 0.25 m s^{-1} versus during the light riming periods. In the WSM6 simulations, an increase in predicted snow mass and larger particles inferred from radar reflectivity contributes to an overall increase in mean fall speeds. Excessive fall speeds above 5 km in WSM6 likely result from erroneously large particles associated with simulated reflectivity greater than observed by the MRR and WSR-88D.

The MORR and THOM2 schemes produce vertical profiles of modal fall speeds for the moderate riming periods similar to their performance during light riming periods despite increases in snow and graupel content (Figs. 9 and 13). In WSM6, the modal fall speeds increase between 6 and 2 km but do not change much above or below that layer. The inference is that increases in snow content from additional riming did not translate to increases in fall speeds through changes in their diameter-fall speed relationships. In addition, cloud water is likely underpredicted during moderate riming events, contributing to an underprediction of fall speeds at lower levels even if the schemes accounted for varied riming conditions. In SBU-YLIN, riming effects are allowed to influence fall speeds, but excessive cloud water contributed to high riming factors and exacerbated fall speed errors previously observed in light riming events (Fig. 6b). These errors resulted in isolated occurrences of fall speeds of $1.5-3 \,\mathrm{m \, s^{-1}}$, composing as much as 15% of the fall speeds in the lowest 1–2 km (Fig. 13e).

c. Surface size distribution and fall speed

In Figs. 14–16, we compare observed and simulated surface size distributions and fall speed measures for four short cases from 1 to 4 h in duration. These cases highlight some details of the representation of particles as a function of the degree of riming and whether aggregation is present. The BMP scheme size distributions are average values for the set of 15-min intervals in each case and are compared to the observed distribution of PARSIVEL diameters (section 2a). For context, we also show average mixing ratio profiles for snow, cloud water, and graupel in the lowest 3 km. We compare distributions of PARSIVEL fall speed (or settling speed, w = 0 and $E \neq 0$; Table 1), to a computed mean mass-weighted fall speed (w = 0, E = 0; Table 1) for each 15-min model-simulated period that includes contributions from snow, graupel, and rain.

1) NO RIMING

A period of mainly cold-type crystals (51% side planes and 20% bullets) occurred from 0145 to 0500 UTC on 16 February 2010, with little or no riming observed. Small

FIG. 8. CFADs of observed reflectivity (dBZ) for light riming periods shown in Fig. 2. Results are shown for the (a) MRR and (b) WSR-88D at OKX. Simulated reflectivity (dBZ) from the (c) MORR, (d) WSM6, (e) THOM2, and (f) SBU-YLIN schemes. The dashed lines at 5.25 km in (a) and 6 km in (b) indicate the altitude at which point the observed CFADs were truncated aloft as a result of the limited number of observations above these altitudes, as described in section 2b.

FIG. 9. CFADs of fall speed variables (positive downward, $m s^{-1}$) for light riming periods shown in Fig. 2. (a) Doppler velocity observed from the MRR, and (b) computed mean reflectivity-weighted fall speed simulated from the (b) MORR, (c) WSM6, (d) THOM2, and (e) SBU-YLIN schemes. The dashed line at 5.25 km in (a) indicates the altitude at which point the observed CFADs were truncated aloft because of the limited number of observations above these altitudes, as described in section 2b.

FIG. 10. As in Fig. 3, but for moderate riming periods shown in Fig. 2.

amounts of plates ($\sim 10\%$) and columns ($\sim 10\%$) were also observed with light riming. The observed and simulated size distributions for this period are illustrated in Fig. 14a. All four BMPs slightly underestimate the number concentrations of aggregated snow particles with D <8 mm, with the MORR and SBU-YLIN results closest to the observed for diameters from 6 to 8mm. Each scheme simulates between 0.1 and $0.15 \,\mathrm{g \, kg^{-1}}$ of snow above 1km, but decreases the amount to around $0.05 \,\mathrm{g \, kg^{-1}}$ at the surface (Fig. 14b). This reduction results from sublimation, since these cold-type habits are mainly observed near the outer edges of the comma head (Colle et al. 2014), where the low levels are still moistening. The reduction in snow mixing ratio near the surface may contribute to an overall reduction in particle number concentrations, as shown by BMPs that predict lower number concentrations of particles across all observed size bins.

The observed fall speed distribution is generally between 1 and $1.5 \,\mathrm{m \, s^{-1}}$ (Fig. 14c). The MORR and SBU-YLIN schemes have particle fall speeds clustered around 1 m s^{-1} , with a few values at $\sim 1.25 \text{ m s}^{-1}$ (Fig. 14d), while the WSM6 and THOM2 schemes produce fall speeds slower than the peak in the observations, ranging from 0.5 to $0.75 \,\mathrm{m \, s^{-1}}$. These schemes simulate a small amount of cloud water ($<0.05 \,\mathrm{g \, kg^{-1}}$) above 1 km (Fig. 14b). There was little riming observed during this event as well, so the observed fall speeds $(tail > 1.5 \text{ m s}^{-1})$ are likely related to faster falling coldtype crystals compared to the conventional plates and dendrites used in these schemes. Underestimation of surface fall speeds in this sample of observed crystals is comparable to the underestimate of fall speeds in the broader sampling of light riming simulations (Fig. 9); therefore, schemes may not be accounting for faster fall speeds for cold-type crystals. The SBU-YLIN includes a temperature-dependence term for fall speeds, but it is based on the local temperature and not necessarily where the snow particles are formed, and the observed side planes and bullets are likely formed in the middle and upper levels of the cloud.

2) LIGHT-TO-MODERATE RIMING

A mix of 70% plates and 16% side planes was observed from 1000 to 1200 UTC on 21 February 2011 with observed riming intensities that range from none to moderate, with the peak riming intensity occurring at 1115 UTC. The WSM6 scheme slightly underestimates the number concentrations of particles across all sizes, and the SBU-YLIN simulates a greater number concentration of particles than was observed for all sizes, with the exception of particles around 2 mm (Fig. 15a). The MORR and THOM2 schemes produce number concentrations of particles similar to the observations for diameters 1 mm or greater (Fig. 15a).

Each scheme simulates snow mixing ratios of 0.15- $0.25 \,\mathrm{g \, kg^{-1}}$ near the surface (Fig. 15b) and the SBU-YLIN scheme has a small amount $(<0.05 \,\mathrm{g \, kg^{-1}})$ of cloud water between 1.5 and 2 km. However, in general, all schemes have very little cloud water, which likely contributes to the lack of fall speeds greater than $1.5 \,\mathrm{m \, s^{-1}}$ (Fig. 15d). Most of the observed fall speeds in this 2-h period were between 1 and 1.5 m s^{-1} (Fig. 15c). All BMPs concentrate their fall speeds around 1 m s^{-1} (Fig. 15d), while the observed peak was slightly greater at $\sim 1.1 \,\mathrm{m \, s^{-1}}$ (Fig. 15c). The small amount of cloud water within the SBU-YLIN scheme resulted in an increase in the diagnosed riming factor for the precipitating ice class and some of the greater fall speeds. This also likely contributes to larger standard deviations in the particle size distribution when the scheme transitioned from between periods of rimed and unrimed precipitation.

3) LIGHT-TO-MODERATE RIMING AND MANY AGGREGATES

Figure 16a shows the observed and simulated size distributions for a time period with 65% dendrites and

FIG. 11. As in Fig. 4, but for moderate riming periods shown in Fig. 2. Note that the *x*-axis scale for the snow or precipitating ice column differs from the remaining panels.

20% plates observed from 1530 UTC 26 February to 0000 UTC 27 February 2010. During this period the observed degree of riming is light to moderate (0.5–2.5) and many aggregates of dendrites are also observed (not shown). The particle size distributions from the examined BMPs are similar to the observed size distributions for particles smaller than 4 mm, but the BMPs underestimate the number concentrations of particles larger than 4 mm. The particle size distribution from the MORR scheme produces slightly larger particles than the other BMPs and, thus, a better fit to the observations. One hypothesis for the underestimation of the number concentrations of larger (D > 4 mm) particles is a poor representation of snow aggregation, or the shift to particle size distributions composed of larger particles at the expense of smaller crystals (Fig. 16b). Each scheme produces $0.05-0.1 \text{ g kg}^{-1}$ of snow below 1 km but varied in their production of cloud water, ranging from 0.05 to 0.15 g kg^{-1} of cloud water between 1 and 2 km. Riming of snow is implied by the collocation of snow and cloud water in the models. An increase in snow content rather than cloud water might have contributed to larger numbers of larger particle sizes in the modeled size distributions.

FIG. 12. As in Fig. 8, but for moderate riming periods shown in Fig. 2.

Unlike the above cases and the combined CFAD results, the THOM2, MORR, and SBU-YLIN schemes are able to produce more cloud water $(0.05-0.15 \text{ g kg}^{-1})$. The distribution of observed fall speeds peaks at

between ~ 0.75 and $\sim 1.1 \text{ m s}^{-1}$ (Fig. 16c), with a tail to fall speeds exceeding 2 m s^{-1} . Model-simulated fall speeds are clustered between 0.8 and 1.1 m s^{-1} (Fig. 16d). The better fall speed prediction in the model,

FIG. 13. As in Fig. 9 but for moderate riming periods shown in Fig. 2.

including some fall speeds greater than 1 m s^{-1} , is likely the result of better simulation of the cloud water. The scheme with the least amount of cloud water (WSM6) has the worst fall speed prediction near the surface (peaking around $0.8 \,\mathrm{m\,s^{-1}}$). The THOM2 has several periods with fall speeds from ~ 2 to $3 \,\mathrm{m\,s^{-1}}$ for mixing ratios below $0.1 \,\mathrm{g\,kg^{-1}}$ (Fig. 16d). These faster fall speeds result from trace amounts of faster-falling

FIG. 14. Period of 51% side planes and 20% bullets observed from 0145 to 0500 UTC 16 Feb 2010. (a) Observed and simulated surface size distributions; (b) mean mixing ratio for snow, cloud water, and graupel (g kg⁻¹); (c) the distribution of PARSIVEL settling speeds, V_s (m s⁻¹), normalized to the number of particles every 15 min; and (d) the mean massweighted fall speed, V_m (m s⁻¹), for total precipitation mixing ratio (snow, rain, and graupel, g kg⁻¹). Error bars represent one standard deviation above and below the simulated size distribution. The diameter for (a) notes that the panel compares the "PARSIVEL diameter" for observations discussed in section 2, and the diameter of assumed, spherical, and frozen hydrometeors within the model, where schemes assume a single crystal habit.

graupel, or the brief production of drizzle with 0.005– 0.01 g kg⁻¹ of rainwater simulated at the surface between 2215 and 0000 UTC (not shown). Aggregates and lightly rimed snow likely composed the smaller peak ($\sim 0.75 \text{ m s}^{-1}$), while the moderately rimed habits likely fell within the second peak ($\sim 1.1 \text{ m s}^{-1}$) and the tail of higher fall speeds. As observed in the CFAD analysis, larger riming factors in the SBU-YLIN scheme contribute to faster fall speeds of 1.25–1.75 m s⁻¹ for predicted snow mixing ratios less than 0.1 g kg⁻¹ (Fig. 16d).

4. Conclusions

Reflectivities and fall speeds from four BMPs (MORR, WSM6, THOM2, and SBU-YLIN) run down to 1.33-km grid spacing within the WRF Model were compared to vertically pointing radar observations at Stony Brook, New York, for nine snow events that were partitioned into periods of observed riming intensity.

Comparisons of observed and modeled particle size distributions and fall speeds at the surface were made for selected periods with distinct sets of crystal habits. Motivating research questions sought to examine whether the selected schemes were able to reproduce key characteristics of the observed distributions of reflectivity and fall speed within various categories of observed riming. During light riming periods, the WSM6 and MORR schemes produced larger reflectivities (Z) than observed, particularly in the lowest 4 km, where they produced higher-density graupel particles inconsistent with the light degree of riming observed at the surface. The THOM2 scheme only produced trace, insignificant amounts of graupel and the SBU-YLIN scheme limited the occurrence of higher riming factors, with a better representation of observed WSR-88D reflectivity in the surface-4-km altitude range. These results encourage a more detailed examination of graupel sources within the WSM6 and

FIG. 15. As in Fig. 14, but during a period of 70% plates and 16% side planes observed from 1000 to 1200 UTC 21 Feb 2011.

65% Dendrites and 20% Plates; 1530 UTC 26 February 2010 to 0000 UTC 27 February 2010

MORR simulations to reduce the generation of higherdensity graupel particles in periods of observed, light riming. For fall speed variables, MRR observations captured a consistent mode around 1 m s^{-1} in the lowest 1–2 km. The THOM2 and SBU-YLIN schemes produced a consistent mode in the same range, but underestimated fall speeds by around 0.25 m s⁻¹. An analysis of the 16 February 2010 event suggests that this may be related to the underpredicted fall speeds of cold-type snow habits.

During moderate riming, the THOM2 and SBU-YLIN results were both closer to Z observations in terms of the most frequent and maximum values at varying altitudes. The MORR and WSM6 simulations produced modal and maximum values of Z that exceeded the observations. As in light riming cases, the MORR and WSM6 schemes produced higher-density graupel within the lowest 4 km, which may contribute to their much higher than observed values of radar reflectivity. The MORR, WSM6, and THOM2 schemes increased the amount of cloud water between 1 and 4 km as the observed riming intensity increased from the light to moderate categories, but the amounts were less than expected for moderate riming, based on previous field studies. The SBU-YLIN scheme produced the largest mean cloud water profile and infrequent occurrences of higher cloud water amounts from 4 to 6 km, contributing to an increase in particle density and a slight overestimation of the radar reflectivity.

There was relatively little change in the near-surface fall speeds with increasing riming category among the MORR, WSM6, and THOM2 simulations, and as a result modeled fall speeds underestimated MRRobtained surface fall speeds by $0.25-0.5 \,\mathrm{m \, s^{-1}}$. These schemes may not produce enough cloud water during these winter storms to capture the observed riming processes (e.g., there is little cloud water in the THOM2 scheme), or the snowfall speeds do not account for increases in particle fall speeds during observed moderate riming periods, likely because they assume dry snowfall speeds unless the scheme contributes mass to the graupel category. The THOM2 and WSM6 schemes incorporate temperature-dependent particle size distribution characteristics for snowfall that provided an increase in fall speeds approaching the surface but were $\sim 0.25 - 0.50 \,\mathrm{m \, s^{-1}}$ slower than the surface observations. The MORR and THOM2 simulations produce similar fall speed distributions with height regardless of riming category.

Comparisons between surface and simulated particle size distributions suggest that while BMPs simulate reasonable number concentrations of particles smaller than 4 mm, there was an underestimate of the number concentration particles larger than 4 mm. It is hypothesized that underestimation of the number of larger particles results from BMPs not adequately simulating the aggregation process, or by allowing for particle size distribution parameters to evolve to smaller intercept and slope parameters as aggregation occurs. Fixed parameters of density and spherical shape may be a limiting factor, though schemes such as THOM2 and SBU-YLIN that incorporate variable bulk density did not markedly improve performance. Lower-density aggregates cannot be well represented in a BMP that assumes a fixed density for snow, such as was used in the WSM6 and MORR schemes. However, the double-moment MORR scheme seemed to provide a better comparison to the observations than other schemes during periods of aggregation, perhaps benefiting from greater flexibility in the determination of size distribution parameters by predicting both the mass and total number concentration. Schemes that predicted higher-density and more heavily rimed graupel particles during light and moderate riming periods resulted in excessive radar reflectivity contrary to radar observations and the lack of these heavily rimed particles at the surface. However, schemes that produced more unrimed snow were not able to capture increases in fall speed during observed moderate riming periods, suggesting that they were unable to predict the observed changes in riming degree.

For schemes that favor the production of higher-density graupel rather than unrimed snow, future work should examine opportunities for a smoother transition between the dry and heavily rimed ice categories to improve the representation of a broader range of riming categories. Additional vertical levels should be included to better capture convective-scale processes contributing to the development of cloud water or small-scale microphysical variability. Such an examination would be best achieved with detailed in situ observations from multiple riming regimes to guide improvements, supplemented by additional radar remote sensing comparisons where in situ data are unavailable.

Acknowledgments. The authors thank Spencer Rhodes for assistance with the processing of MRR data. Financial support for this research project was given by the National Science Foundation (ATM-1347491 for BAC and ATM-1347499 for SEY), as well as the NASA Precipitation Measurement Missions Program (NNX13AF88G for BAC and ALM). A special thanks to Dr. Gordon Taylor for allowing us to use his microscope and camera throughout the observational portion of this study. The authors also thank three anonymous reviewers who provided suggestions that improved the clarity of discussions and the related figures.
